Cyclic behaviour of saturated sands subject to previous horizontal shear stresses
Comportement cyclique des sables saturés soumis à des contraintes précédentes de cisaillement horizontal

ABSTRACT
The dynamic behaviour of saturated sands has been studied from different perspectives. However, most experimental research on this field does not take into account the shear stress conditions existing prior to the application of dynamic loads; i.e., a null initial static shear stress (σ₀ = 0) is assumed. The main objective of this work is to report on the influence that static shear stresses (σ₀) have on the behaviour of saturated sands under cyclic shear loads. This article presents the results and analysis of part of a wider experimental programme involving 30 monotonic and 26 cyclic simple shear tests for different combinations of static shear stress (σ₀) and cyclic shear stress (σ c) (all undrained), besides identification and classification tests. The tested samples have been taken from the area of the North Entrance Mouth at the Port of Barcelona (Spain).

RÉSUMÉ
Le comportement dynamique des sables saturés a été étudié sous différents angles. Cependant, la plupart des recherches experimentales sur ce sujet ne prennent pas en compte les conditions de contrainte de cisaillement existants avant l'application des charges cycliques, c'est à dire, on a considéré une contrainte de cisaillement statique initiale nulle (σ₀ = 0). L'objectif principal de ce travail est de rapporter sur l'influence que cette contrainte de cisaillement statique a sur le comportement des sables saturés sous des charges cycliques de cisaillement. Cet article présente les résultats et l'analyse d'une partie d'un programme expérimental plus important, comprenant 30 essais monotones et 26 essais cycliques de cisaillement simple pour différentes combinaisons de contraintes de cisaillement statiques (σ₀) et cycliques (σ c) (tous non drainés), en plus des essais d'identification de classification. Les échantillons testés ont été prises à l'Embochurte Nord du Port de Barcelone (Espagne).

Keywords: saturated sand, cyclic shear tests, static shear stress, cyclic stress ratio, liquefaction, harbour caissons

1 INTRODUCTION
This paper summarizes a research on the dynamic behaviour of granular soils under undrained conditions. This situation has predominantly been studied, for example, by Park and Silver [5], Dobry and Ladd [6], Dobry et al. [7]; whereas cyclical tests on drained sands are somewhat less frequent: Silver and Seed [8],

¹ Corresponding Author.

A very complex phenomenon not yet fully understood is that of “liquefaction”, thoroughly studied by Seed and Lee [2], Castro [12], Casagrande [13], Seed [14], [15], Kramer [16], Ishihara [17], Youd [18], Boulanger and Idriss [19], etc. It may affect saturated granular materials and consists in total loss of shear strength under dynamic actions, as a consequence of rapid and progressive increase of pore pressures.

A research into granular soil strength is presented here, with a view to help evaluate the safety of harbour caissons in vertical breakwaters. The foundation ground under a caisson is subject to different stress conditions, as Figure 1 shows.

However, most of the previous experimental research has been limited to simulating a material with null horizontal shear stress ($\tau_{ho} = 0$) prior to applying the cyclic shear loads. This is but a particular case from the range shown by Fig. 1.

![Figure 1. Idealized stress conditions along a hypothetical failure line](image)

This article presents results of cyclic simple-shear tests, for various combinations of initial horizontal shear stress ($\tau_{ho}$) and cyclic shear stress ($\tau_{c}$), and analyses how this combination ($\tau_{c} - \tau_{ho}$) influences sand behaviour and strength. To this end, a procedure much like the one that Patiño [20] and Patiño and Soriano [21] suggest for evaluating the cyclic behaviour of cohesive materials.

2 EMPLOYED EQUIPMENT

The apparatus for cyclic direct simple shear (DSS) tests at the Soil Mechanics Laboratory of the Escuela Técnica Superior de Ingenieros de Caminos, Canales y Puertos (ETSICCP) of the Universidad Politécnica de Madrid (UPM), which was employed for this investigation, is computer-controlled and was manufactured by Wykeham Farrance, a division of Controls Group. It can be seen in Figure 2 and a full description be found in [22].

![Figure 2. Cyclic DSS equipment used for the tests.](image)

3 TESTED MATERIAL

The tested samples were taken by means of three boreholes drilled from the dyke on the North Entrance Mouth at the Port of Barcelona, Spain. The average borehole depth was 21 m under the seabed.

The geological origin of the area is sedimentary: an alternation of clayey silts, silty clays and silty sands. In general, the deposits can be characterized as conchiferous and micaceous.

The total number of undisturbed samples taken for the experimental stage of this research is shown in Table 1, but this article only deals with the dynamic behaviour of silty sand samples. It was assessed by 6 monotonic and 17 cyclic simple shear tests.
Table 2 shows the index properties of silty sand samples tested with the shear apparatus. Shear strength parameters have been obtained for a limit shear deformation of 10% and assuming $c = 0$.

The dynamics tests, for analysing the combination of prior static shear stress ($\tau_u$) and the cyclic shear stress applied ($\tau_c$), were made with different ratios between these values and the in-situ effective consolidation pressure, $\sigma'_{ov}$. The following couples of $(\tau_c/\sigma'_{ov} - \tau_u/\sigma'_{ov})$, in percentage, were used: (0-5), (0-10), (0-15), (0-20), (5-15), (10-20) and (15-5).

To make all tests consistent, they were performed under these conditions:

- Undisturbed samples.
- Specimens were 70 mm in diameter and 19 mm in height.
- The test effective consolidation pressure was the same as the in-situ vertical effective stress ($\sigma'_{ov}$). As sampling was done from boreholes drilled through the caissons of the already-existing dyke, the increase in effective pressure due to the caisson weight was added to that from the soil own weight.
- Undrained conditions with evaluation of generated pore pressure. According to Bjerrum and Landva [23], constant-volume simple shear tests are equivalent to undrained tests and the change in vertical pressure applied on the specimen is equal to the change in pore pressure that would undergo a specimen under an undrained simple shear test with constant axial stress.
- Controlled stress, during the cyclical loading stage. Sine wave with an amplitude equal to the cyclic shear stress ($\pm \tau_c$) and a period of 15 seconds.
- Controlled strain rate, during the monotonic loading. The shear deformation rate was 0.015 mm per minute, which equates 4% per hour.

4 ANALYSIS OF RESULTS

4.1 Number of cycles to failure

Cyclic simple shear tests have stopped when liquefaction occurred (condition A), when angular deformation reaches 15% (condition B) or the number of cycles reached 1300 (condition C).

Figure 3 shows the type of condition motivating the end of tests. It seems that the value of prior shear stress has an influence on this matter. For the same value of maximum shear stress ($\tau_{\text{max}} = \tau_u + \tau_c$), liquefaction has only occurred in tests with low values of $\tau_u$.

![Figure 3. Type of condition that led to stopping the test and number of tests done.](image)

For small cyclic stresses and within the range of initial stresses being explored, no liquefaction or excessive strain occur; the end of tests is controlled by the maximum number of cycles.

In the diagram of Figure 3, it seems that some borderlines may exist, which would indicate the regions for each condition. The lower region, C, could be considered stable; the intermediate region, B, could correspond to failure due to large strain; only in region A, sudden liquefaction would happen at a certain moment. For the condition of $\tau_u = 0$, when liquefaction occurs, the ratio between the...
number of cycles and the cyclic stress ($\tau_c$) is shown in Figure 4.

![Figure 4. Number of cycles needed to cause failure for different stress conditions](image)

4.2 Stress-strain behaviour

Figure 5 shows the typical stress-strain behaviour for the different combinations of ($\tau_c/\sigma_{ov}' - \tau_c/\sigma_{ov}^*$).

![Figure 5. Typical stress-strain curves for different combinations of ($\tau_c/\sigma_{ov}' - \tau_c/\sigma_{ov}^*$).](image)

The shear modulus ($G$) corresponding to each cycle varies along the test, as Figure 6 shows. It can be seen that this modulus is a function not only of the number of cycles ($N$) but also of the combination ($\tau_c/\sigma_{ov}' - \tau_c/\sigma_{ov}^*$). For the same ($N$) and ($\tau_c/\sigma_{ov}^*$), ($G$) decreases when ($\tau_c/\sigma_{ov}'$) grows. Apparently, a prior static stress ($\tau_c/\sigma_{ov}^*$) induces a cer-
tain stiffening in the soil, and can even modify its behaviour. The clearest proof of the influence of the combination \((\tau_c/\sigma_w' - \tau_c/\sigma_w')\) arises when comparing the pairs (0-20) y (15-5), for both of which \((\tau_c/\sigma_w') + (\tau_c/\sigma_w') = 20\%\). For the pair (0-20), (G) decreases from 4 to 1 MPa in 9 cycles, whereas (G) increases from 9 to 12 MPa in 1300 cycles for the combination (15-5).

4.4 Pore pressure (u)

Figure 8 represents the trends of variation of the pore pressure generated during the dynamic loading. Besides combinations (0-5) and (15-0), in the remaining cases the ratio \((\Delta u/\sigma_w')\) was larger than 85\%, which led to degradation of the soil stiffness and therefore to large cyclic and/or permanent strains. In cases (0-5) and (15-5), this ratio was 50\% at most, after 1300 cycles.

5 CONCLUSIONS

It is well known that the cyclic stress ratio \((\tau_c/\sigma_w')\) is a governing factor in dynamic behaviour of soils. However, on the basis of this research results, it can be stated that soil behaviour is also controlled by the ratio \((\tau_c/\sigma_w')\).

The value of initial shear stress \((\tau_c)\) significantly influences the type of failure that takes place in tests. It affects the ranges of variation of shear modulus (G) and damping (ζ), the development of cyclic \((\gamma_c)\) and permanent \((\gamma_p)\) strains and pore pressure generation.

Taking into account that the combination \((\tau_c/\sigma_w' - \tau_c/\sigma_w')\) governs the development of cyclic and permanent strains, some soil regions under a structure would tend to reach failure due to cyclic deformation and other regions due to permanent strain. However, the needed compatibility of strains along a failure line prevents these two regions to be adjacent. Therefore, a re-distribution of stress must
occur, also controlled by the combination \((\tau_0/\sigma'_{ov} - \tau_c/\sigma'_{ov})\).

For the particular material tested, small cyclic strains are developed while the ratio \((\Delta u/\sigma'_{ov})\) is < 80%; for larger values, the generation of cyclic strains accelerates – they even can go from 14% to 60% in a single cycle.

ACKNOWLEDGEMENTS

The authors would like to thank Puertos del Estado, for financing this work; the Autoridad Portuaria de Barcelona, for providing the needed soil samples; the Universidad Politécnica de Madrid - and particularly the Escuela Técnica Superior de Ingenieros de Caminos, Canales y Puertos-, for making the experimental research possible.
